? Cremolita perluta, var, affieis, Miers, Ann. Mag. Nat. Hist., (5), v., $1880, \mathrm{p} .372, \mathrm{pl}$. xiv., fig. \& (fide Ortmama).

Obs-Ortmann has included under the heading of $C$. spinosus a variety differing from the typical form in having the dactyli of the third left legs less slender, and flatened extornally. Following Dana, he determincd this variety as $C$. olicieri, Owen, but a reference to the original description and Olivier's figure of that species shows that it has the dactyli rounded and spiny as in the typical $C$. spinosus, and the name therefore cannot be applied to thoses in which they are smooth and flattened. I therefore propose the new name variabilis for the variety in which the two last joints of the third left legs aresmooth and flattened externally, and the hand of the lager cheliped is nearly smooth, and with an oblique row of larger granules on its upper exterior surface.

[^0]The following notes and the accompanying plate show the great range of variation in the characters, usually rolied upon to differentiate the species of this genus, as presented by a splendid series of C. spinosus from Cape York, N. Australia.

The gastric region may be strongly convex or flattened, and the width of the front varies between 3 and 3.5 in the leneth of the carapace. The length of the eyes is also variable. The hand of the larger cheliped may be intensely spiny, or the lower portion of the outer surface may be jerfectly smooth, and a more or less distinct stridulating ridge on the upper part may he present or absent. The propodus and dactylus of the second and third, or third only, pairs of left legs may be sub-cylindrical and long, or markedly llattened and shorter. If flattened, there is a prominent crest on the upper and lower posterior margins of the dactylus, and sometimes also on the distal portion of the propodus.

Great as these variations seem, they are certainly within the limits of the one species, as I found all my specimens living together under a sheet of bark at Cape York, and they form an unbroken serics between the two extremes I have figured. Further, though they would suggest that the variations are due to the age of the individuals (young, variabilis ; adult, spinosus), ot her specimens in the Museum collection from the north-west coast of Australia, Murray Islands, Torres Straits, the Eiji Islands, and the New Hebrides show that this supposition is incorrect.

As Birgus lirsutus, Hess has recorded this species from Sydney. This is, however, certainly wrong, as the genus is confined on the eastern coast of Australia to North Queensland. For the same reason, Heller's record ${ }^{1}$ of C. rugosus, M. Edw., from Sydney, is incorrect.

Leander serenus, Ieller.
(Plate lxxxix., figs. 9-12.)
Leander serenus, Heller, Reise Novara, Crust., 1865. p. 110, pl. x., fig. 5. Kd. Haswell, Cat. Austr. Crust., 1882, p. 195.
Palcmon affuis, Bate, Chall. Rep., Zool., xxiv., 1888, p. 782, pl, cxxviii., fig. 5 (uec. P. a/jinis, M. Edw.).
Carapace smooth and polished. The rostrum is very variable in shape, being either broad or narrow, and its upper margin nay be almost straight, or else bent upwards towards the tip. It is armed with six to nine nearly equidistant teeth above, and three

[^1]or four below, those near the apex generally placed near one another, so as to give it a bi- or tridentate appearance; the posterior two or three teeth are placed over the anterior part of the carapace. The antennal and branchiostegal spines are well developed, the latter being placed rathor behind the vertical of the other, but overlapping the anterior border of the carapace.

Antennular peduncles not quite so long as the rostrum, their flattoned outer portions armed each with a terminal and median spine. The two extemal flagella are united for ahout one-third the length of the thickened flagellum, the outer margin of which is olscurely serrated, The basal joint of the antennal peduncle with a strong external spine; the flagellum about as long as the entire body.

The extemal maxilipeds extend a little beyond the antemal peduncles, and their exopods are large and reach to the ends of the ante-penultimate joints.

The first pair of legs are very slender and reach a little beyond the tip of the scaphocerite. The second pair are large and cylindrical, and, when fully developed, extend almost as far as the tip of the inner antennular flagellum. The merus does not reach so far forward as the end of the scaphocerite. The carpus is thickened distally, and is slightly longer than the palm, its length varying a little with age. The palm is swollen and onethird longer than the fingers.

The three posterior pairs of legs are sulequal in length, slender, cylindrical, and, with the exception of a row of minute spinules on the lower border of the propodus, are unarmed. Short brushes of setre overhang the bases of the dactyli, and there are scattered bristles on the carpus and propodus of each leg.

The telson terminates in an acute spine, on either side of which is a long internal and short external one, both being movable. Two pairs of spinules are placed on the hinder half of the upper surface.

Obs.-Miers ${ }^{2}$ regarded L. serenus as a variety of $L$. intermedius, but it is readily distinguished from that species by the branchiostegal spine being placed on the margin of the carapace, and by the different proportions of the carpus and propodus of the second legs.

There can be no doubt that the specimens from Port Jackson determined by Spence Bate as Palcmon affinis, M. Edw., are not

[^2]that species, as was sugrested by Ortmam," but are ilentical with the above. The late Mr. F. E. Grant, when in lingland. compared Victorian specimens of $I$. serenns with the "Challenger" specimens and found them to be identical.

Ifab.-I have collected thisspecies in rock-pools at Rat Island, Port Curtis, and aromd sybney, and thare are specimens in the Anstralian Museum collected by Mr. J. Gabriel in Port Phillip, Victoria.

Lmaner motredes, sp. now.
(Fig. 16.)
Obs.-Compared minutely with h. seronu, this species appears to be distinguished by the following important chamacters alone.

The two external flage da of the antenmules are mited only at their bases, six or seven juints being joined, while twenty-seven or more form the free portion of the thickened flagellum, which is distinctly serrated on its outer edge.

Fig. 16.
The second pair of legs are much shorter, reaching in my largest specimen only a trite beyoud the thickened antemulat liagellum. The carpus is much thickened distally and is shorter than the palm, and does not extend to the tip of the scaphocerite. The palm is thick and swollen, and is not mach longer than the fingers.

Four specimens from rock-pools on the coast near Sydney. Largest specimen measuring 39 mm . from the tip of the rostrum to that of the telson.

3Ortmann-Kool, Jahrl. Syst., V., 1890, 1. 521.

From L. natator, M. Ediw., to which this species is closely allied, it is distinguished by the different proportions of the joints of the second pair of legs and in having a greater number of joints in the thickened antennular flagellam.

## Leander intermedies, stimpson.

(Plate lxxix., fiss. 13-14.)

Leander intermedius, Stimpson, Proc. Acad. Nat. Sci. Phil., sii., 1861, p. 41. Id. Haswell, Cat. Austr. Crust., 1882, p 195. Id. Ortm unn, Zool. Jahrb. Syst., v., 1890, p. 523. Id. Grant in Sayce, Vict. Nat., xviii., 1902 , p. 155.

Carapace smooth and polished. Form of the rostrum variable, straight or bent upwards and extending nearly or quite as far forward as the scaphocerite. There are six to nine teeth whove and four or five below, those near the apox placed so close together as to give the tip a bi- or trifid appearance. The posterior two or three teeth are placed over the anterior part of the carapace. The antemal and branchiostegal spines are well developed, the latter being placed well behind the vertical of the other, and at some distance from the anterior margin of the cumpace.

The antemular peduncles are not so long as the rostrum, and the outer margin of their flattenced portion is armed with a terminal and median spine. The two external flagella are united for rather more than one-third the length of the thickened flagellum, the outer margin of which may be obscurely serrated. The basal joint of the antemal peduncle has a strong spine at its outer angle, and the flagellum is about as long as the entire body.

The external maxillipeds extend a little beyond the antennal peduncles, and their exopods are large and reach to the ends of the ante-penultimate joists.

The first pair of legs are very slender and reach to, or a little beyond the tip of the scaphocente. The second pair are more slender than those of $L$. serenus and are somewhat shorter, the end of the carpus in my largest specimen being but little in advance of the tip of the rostrum. The carpus is thickened distally and is much longer than the palm, being, in young specimens, equal to the length of the whole hand. The palm is swollen, and is only a little longer than the fingers.

The three posterior pairs of legs are very slender, and the fifth pair is rather longer than the third. Except for a row of spinules
on tach propolus, they are unarmed, but there are short brushes of setre overhanging the bases of the dactyli, and scattered bristhes on the carpus and propodus of each leg.

The telson terminates in an acute spine, on cither side of which is a leng internal and short external one, both of which are movable. Two pairs of spinules are placed on the hinder half of the upper surface.

Obs.-Tlis species is readily distinguished from its allies by the position of the hranchiostegal spine. From $L$. seremus it further differs by having the second pair of legs shorter, and the palm being much shorter than the carpus. The ambulatory legs are also more slender than in that species.

Mab.-Common in Port Jackson, where it is found on weedy bottoms. It is also recorded by Miers ${ }^{4}$ from King George's Sound, s. W. Australia, and Tasmania. His specimens from Ovalau, Fiji Group, probably do not belong to this species, and those from Port Molle, Queensland, are possilly L. serenus. Grant records it from Port Phillip, Victoria.

## Rhyncholinetes rugulosus, Stimpson.

> (Plate lxxxix., figs. 1-8.)
hhynchocinetes rugulosus, Stimpson, Proc. Acad. Nut. Sci. Phil., xii., 1860, p. 36 . Id. Haswell, Cat. Austr. Crust., 1882, p. 180.

The surface of the whole body is roughened by very fine and close-set lines which sometimes support a short but dense pubescence. In large specimens these lines are also present on the appendages, but in smaller ones they appear smooth.

The carapace is armed with six large spines; one at the base of the rostrum and a second behind it, a pair of supraocular and a pair of antennal spines. The antero-lateral angle of the carapace is also armed with a minute spinule. The rostrum reaches a trifle beyond the scaphocerite and is inclined upwards towards the end, but its extreme tip is directed downwards. The upper margin bears two large teeth on the posterior half and five or six smaller ones distally, the last being the tip of the rostrum. There are eleven to thirteen teeth on the lower margin, which increase in length backwards to the eighth, those following being shorter and broader, and the last two recurved inwards.

[^3]The antenoular peduncles reach to about the midde of the rostrum, and the shorter Hagellum a little way beyoml its tip. The Hattened basal portion is armed on the outside with a long slender spine, and the joints of the peduncle are provided with brushes of short stiff sete.

The basal antemal joint has a strong spine on its outer angle. The scaphocerite is long and narrow, the flattened portion being obliquely truncate from the tip. The flagellum is a little shorter than the whole body.

The mandibles have a short cylindrical molar process and a large toothed cutting edge. The palp is three-jointed, the last joint and distal portion of the second being densely setose.

The first maxilla are three-branched, the median branch being the longest and with a double row of teeth on its edge. The superior branch is curved and terminates in a short bristle, and the inferior is rounded with setose margins.

The second maxille consist of tive plates and a slender, twisted, median process. The two outer plates forming the branchial fan are the largest, and the hinder one terminates in extremely long seta. All the other plates have their inner margins setose.

The first maxillipeds have also two outer fan-plates, which, however, are not setose. A long jointed lash extends from the inner angle of an oblong, setose plate. The median process is jointed to a thickened basal portion, both being setose.

The basal joint of the second maxilliped supports a small leaflike plate externally, and a long jointed lash springs from the second. The last joint is large and retlexed upon the others, its distal portion being thickened and set with two opposing clusters of bristles which are more numerous than those on the hinder part of the join't.

The external maxillipeds aro very large and setose, and reach beyond the scaphocerite. The merus has a spine at its distal end, and the last joint bears about six black thorns at its tip. The exopod reaches to the end of the merus.

The first pair of legs are comparatively short and thick, and reach beyond the antennal peduncle. The upper margin of the merus ends in a strong spine. The fingers are tipped with three or four black points which interlock when closed. There is a patch of short hairs on the lower surface of the palm.

The second legs are slender and reach beyond the first. Beyond the black thorns on the tips of the fingers they are unarmed.

The ambulatory lers vary somewhat with age, being shorter and thicker in smaller than in larger specimens. 'The first is the longest and reaches to or beyond the scaphocerite. The ischiun is armed with a spinule, and there are three more on the lower exterior margin of the merus. The carpus has wwo spinules, and the lower mangin of the fropodus bears a row of minute spiniform setae. The dactylus also has some teeth on its lower edge. There are seattered sete on the end of the morus and on the following joints. All three pairs of ambulatory legs are similar, exeept in length.

The tekon has three pairs of pinules on its upper surface, and embs in an acute point, on cither side of which are three spimules, the median heing the longest.

Obs.-Whynchocinetes rugutosas is a common species around sydnoy, inhabiting dank crevices between rocks and in weedy pooks. It is very beautifully marked when alive with streaks and dots of a bright blue colour on a darker ground. There are also specimens in the Australian Musenm collection from Lord Howe Island.

Aceording to Stimpson, the anterior part, of the rostrum in the type specimens was tridentate. In all that $T$ have seen there are five or six teeth at the tip of the rostrum. My specimens being from the same locailty as the types, however, phaces their identification beyond doubt.

Rhynchoctuefor tymbs, M. Edw., is included in the Austratian fauna on the authority of Miers," who wrote in the Catalogue of New Kealand Ceustacea that it was found also on the coasts of Austraha and Chili. I have not sern this species, and think that he probably confused it with $R$. rugulosus, Stimp., which, however, appeas to be readily distinguished hy having fewer teeth on the upper and lower margins of the rostrim.

- Having sent Miss M, J. Rathbun a tracing of my figure of $h$. ruguloses for comparison with specimens of $K$. typus, she has very kindly favoured me with the following notes.

The rostrum has seven or eight spines athove, near the tip, and
 spincs below. Maxillipeds longer and more slender; antemal scale not reaching the last segment of the maxilliped. Carpus of the first leg less than half as long as the propodus, and equal to the dactylas in length; margins of the pralm not convex. Second leg very little longer than the first ; propodus about fourfifths as long as the carpus and not stouter than that joint.

[^4]Alope australis, Beder.
Alope parpulis, ITaswell, Cat. Austr. Crust, 1882, p. 193 (nec. White).
Alope onstralis, Baker, Trans. Roy. Suc. S. Anstr., xxviii, 1904 , p. 154, pl. xxx, figs. 1-7.
$O b$.--This is a very common species in rock-pools near sydney. Mr. W. A. Baker has kindly compared specimens from here with his types, and confirms my identification. He adds that he has overlooked the division of the ischium and merus of the second jereiopoda into two joints each, they heing olscure in his specimens.

Mr. C. MI. Thomson has also compared others with those used by him when writing upon A. pralpalis, White," and he has favoured me with the following notes and sketches of the rustrum of both species.

The rostrum of $A$, australis (fig. 17, 1) is shorter than that of the New Kealand species, and is armed with six terth above, as against $3-45$ teeth in A. puelpatis (fig. 17,2-3). It is also a much smaller species, the largest specimens being on and ahalf inches long, while A.polpolis attains two or three inches in length. A. australis is marked with darker spots and bars, while A. putpelis is of a

Fig. 17. uniform whitish colour.

The rostrum of $A$. australis is also subject to some variation, some of my specimens having only four or five teeth; but they are always egaally spaced and not separated by wide gaps as in the figures of $A$. palpalis. It shouid aho be noted that $A$. austredis also fades to a uniform white after lung preservation in spipits.
A. pulpulis is thee efure not an Australim species.

Meptamenes monoceros, Fidricius.
Peuthe monoceros, Haswell, Cat. Austr. Crust., 1582, p. 200.
Metapeneus monoceres, Alcock, Cat. Ind. Det. Crust., pt. iii., 1906, p. J8, pl. iii., t.g. 7.

Pemmen, sp., Whitelegge, Proc. Roy. Soc. N.S. Wales, xxiii, Is90, p. 22.) ; Whitelegqe in Ogilby, Edible Fish. and Crust. N.S. Wales, 1893, p. 203 .
Obs.-Thespecimens recorded by Whitelegge as an undescribert species of Penems are identical with the ahove. Though stated
"Thomson-Trans. I.inn. Soc., (2), viii., 1903, 1. 440 , pl. xxviii., tige.3.12.
to be the commonest species offered for sale, he adds that it is abundant at certain seasons only, and he informs me that all his specimens were secured at the fish-markets by Mr. J. D. Ogilby.

This species has not been previously recognised from N.S. Wales, though Haswell records it from the Endeavour River, Quecnsland.

Eucrate dorsalis, White.
Cancer (Galene) dorsalis, White, Proc. Zool. Soc., 1848 (1849), p. 144, Anmulosa pl. vi.

On page 58 of the present volume I anfortunately described this species under the new name E. hamiltoni. Though no definite locality is given, White states that his specimen was obtained by Mr. John MacGillivaray during the voyage of the "Rattlesnake," and it therefore probably came from N. Eastern Anstralial.
